(Received 16 February 1999)

An abundance of evidence now demonstrates that the growth of epitaxial thin films does not necessarily follow one of the three classical modes (layer-by-layer, agglomeration, two-dimensional growth followed by island growth). A specific example is the case of a metal grown on a single crystalline substrate of much lower surface energy than itself. One monolayer of Ni deposited on Ag(111) or Ag(100), in particular, becomes covered by one or two layers of Cu upon annealing to 770 and 620 K, respectively [1,2]. Theoretical calculations [2–4] predict, moreover, that these capping layers remain on top during further deposition. Monte Carlo simulations [5] show that a Ni monolayer upon annealing to 620 K spreads over six to seven subsurface layers in the form of clusters with (111) and (100) facets which contain about 100 atoms. Similar behavior was observed when 20 monolayers of Co were epitaxially grown on Cu(111) or Cu(100) at room temperature [6]. Upon annealing to 670 K, a capping layer of Cu formed by diffusion of substrate Cu atoms through “pinholes,” step bands, and the like, onto free surfaces of the Co film [6,7]. In the early stages of this growth, STM studies revealed that Co forms triangular double-layer islands on Cu(111) with a Cu overlayer at 300 K [8,9]. These islands also occupy one subsurface layer. We note that when pure Co is deposited on Cu between 700 and 900 K, a Co-Cu alloy grows on the surface, even though these metals are nearly immiscible in equilibrium [10]. There Cu flows from the bottom of the film through pinholes and mixes with the arriving Co.

This Letter reports on observations of a related but new phenomenon, concerning the deposition of nanoparticles on single crystalline films. We find that Co nanoparticles with diameters of ~10 nm do not remain on the surface of Cu(100) and Ag(100) films when deposited at 600 K, rather they burrow into these substrates. This behavior is fundamentally different from the capping behavior in the work cited above, since it is driven, as we will show, by the exceptionally large capillary forces rather than the differences in surface-free energies. The fact that Co has a larger surface energy than either Cu or Ag predicts only the formation of a thin layer of substrate material around the particles, but not burrowing. We further observe that the Co nanoparticles reorient to become coherent with the Cu matrix as they sink, whereas they become only semicoherent in the case of Ag. These findings imply that burrowing is rather general and that it is in fact a mechanism of surface smoothing that has not been previously considered. Burrowing also has obvious implications for the mobility of clusters on surfaces.

The Co nanoparticles were generated by dc magnetron sputtering of a cobalt target (99.95% purity) in 1.0 Torr of ultraclean argon (<1 ppb) and a baked ultra high vacuum (UHV) chamber (base pressure in the high 10⁻¹⁰ Torr range). This sputter chamber is attached to a UHV compatible transmission electron microscope (TEM) (modified JEOL 200CX [11], base pressure in the low 10⁻⁹ Torr range) via a connecting tube. After sputtering for 30 s in the static argon atmosphere, the argon gas was pumped out through the microscope and the particles were deposited on the substrate. The temperature of the substrate could be regulated with an accuracy of 20 K. Details of the instrument have been described elsewhere [12]. The Cu and Ag substrates were produced as single crystalline films, 50–100 nm thick, by e-beam evaporation on (100) rocksalt in a UHV system. Subsequently, they were mounted on Si support rings and transferred into the microscope. Any possible oxide on the films was reduced in situ: by heating in vacuum to 800 K in the case of Ag, and by heating in methanol vapor at 600 K in the case of Cu [13,14].

Co clusters were first deposited at room temperature on a clean Cu(100) surface in the UHV TEM. The films could be imaged within about one minute of deposition. The particles were randomly distributed, and their size distribution was log normal with a mean particle diameter of 13 nm and a variance of 4 nm. Bright field images
shown in Fig. 1(a) together with dark field images and selected area diffraction patterns (not shown) indicated that the particles were randomly oriented with respect to the substrate. In the diffraction pattern the first four fcc rings were visible. The (220) ring was much stronger than the (200) ring, which indicates a (111) texture of the particles. This agrees with their highly faceted shape seen in bright field [Fig. 1(a)], assuming that they are faceted along (111).

Particles were then deposited with equal coverage on a substrate held at 600 K, which are shown in bright field in Fig. 1(b). Note that the particle size distribution remained unchanged. The vast majority of the Co particles became epitaxial with the Cu(100) film, assuming the substrate orientation. The particles were dislocation free, and, since the lattice constant of Co is 1.9% smaller than Cu, they strained the Cu matrix. Formation of coherent, dislocation-free Co islands on Cu, up to 37.5 nm in radius, was also reported for the vapor deposition of Co onto Cu(100) at 620 K [15]. Notably, the image contrast observed in Fig. 1(b) resembles the image contrast of coherent Co precipitates embedded in a Cu matrix calculated by Ashby and Brown [16], providing initial evidence that the nanoparticles were below the top surface of the film.

Ex situ atomic force microscopy (AFM) scans on the nonelectron transparent part of the TEM specimens, performed in tapping mode, revealed a pronounced difference in the surface topographies for the 300 and 600 K depo- sitions, as seen in Fig. 2(a). Whereas all particles reside on the surface after deposition at room temperature, the majority of them have sunk into the substrate after deposition at 600 K. Energy dispersive x-ray analysis (EDX) and electron energy loss spectrometry measurements confirm that the topography change was due to the Co particles sinking rather than spreading over the surface. Figure 2 also shows that a small fraction of the particles deposited at 600 K did not sink. We attribute this observation to residual contamination on the film. The height to height correlation functions of the two samples shown in Fig. 3(a), \[ H(|\tilde{r}|) = \langle (\hat{z}(\tilde{r}_0) - z(\tilde{r}_0 + \tilde{r}))^2 \rangle \] (the brackets denote an average over all possible \( \tilde{r}_0 \) and a spherical average over \( \tilde{r} \)), have almost identical shapes, but with the rms roughness being reduced by a factor of 2 for deposition at 600 K. There are no correlations in inter-particle distances, again showing that they are randomly located on the surface. It should also be noted that the characteristic length scale derived from these graphs does not correspond to the actual particle size but to the size of the AFM tip. Coverage in the AFM images appears much higher than in the TEM micrographs for this reason.

Despite the lattice mismatch of 13% between Co and Ag, this system behaved very much like Co-Cu. The particles were randomly oriented on the Ag(100) film after deposition at room temperature, while after deposition at 600 K they again assumed the (100) orientation of the substrate. Also, the ex situ AFM measurements on the two samples in Fig. 2(b) show that the majority of the Co clusters sank after deposition at 600 K, but not after deposition at 300 K. The height to height correlation functions [Fig. 3(b)] also show a reduced roughness at 600 K, and no correlation between particles. To further confirm these results, a Ag film with Co clusters deposited at 600 K was prepared in a cross-sectional geometry and analyzed by EDX. Care had been taken to align the surface of the Ag film parallel to the electron beam. The map of the Co EDX signal, illustrated in the top right corner of Fig. 4, shows five Co clusters in the field of view. Line scans of the Co and Ag signal through the particles along the film normal, included at the bottom of Fig. 4, show more clearly that the particles are located just below the top surface of the film, not merely capped by substrate atoms.

The basic driving force for this sinking process is, of course, the reduction in total free energy by exchanging

substrate interface below the surface without increasing
the substrate surface area. This process is likely to occur
in two steps: first, by the coating of the particle with
substrate material, as suggested by Refs. [1–10], followed
by burrowing. We illustrate the savings in free energy by
these two processes for the case of Co particles on Ag. By
coating the Co particle with Ag, the reduction in energy

FIG. 3. Height to height correlation functions calculated from
AFM images of Co on Cu (a) and Ag (b). The characteristic
length scale in both images is around 40 nm and determined
by the AFM tip. Beyond that there is no sign of any
 correlation between particles. All curves rise roughly with the
$r^{1.6}$ dependence expected for a spherical AFM tip. The values
of the rms roughness $\sigma$ are directly comparable within (a) and
(b) since the 300 and 600 K samples of each substrate material
had an identical coverage ($\pm 5\%$).

the Co-vacuum interface above the surface with a Co-
substrate interface below the surface without increasing
the substrate surface area. This process is likely to occur
in two steps: first, by the coating of the particle with
substrate material, as suggested by Refs. [1–10], followed
by burrowing. We illustrate the savings in free energy by
these two processes for the case of Co particles on Ag. By
coating the Co particle with Ag, the reduction in energy

per unit area, $\Delta \gamma$, is

$$\Delta \gamma = \gamma_{\text{Co}} - (\gamma_{\text{Ag}} + \gamma_{\text{Ag-Co}} + \gamma_{\text{chem}}).$$  \hspace{1cm} (1)

The surface energy $\gamma_{\text{Ag}}$ of Ag(100) is 1.2 J/m$^2$ [17],
while for Co we choose the lowest energy surface (0001)
for which $\gamma_{\text{Co}}$ is 2.8 J/m$^2$ [17]. The energy associated
with the semicoherent Co-Ag interface is approximated
by the average of the high-angle grain boundary energies
of Co and Ag, $\gamma_{\text{Ag-Co}}$, 0.6 J/m$^2$ [18], plus an additional
term accounting for the immiscibility at the interface. We
estimate this term, $\gamma_{\text{chem}}$, using the zero-layer model due
to Becker [19], such that $\gamma_{\text{chem}} = 2g\Omega N_S$, where $g$
is a geometric factor ($\approx 1/3$), $\Omega$ is the heat of the mixing
parameter, 0.2 eV/atom [20], and $N_S$ is the area density
of atoms on the interface, $1 \times 10^{19}$ m$^{-2}$. With this set of
values, $\Delta \gamma$ equates to 0.8 J/m$^2$.

By particle burrowing an additional amount $\gamma_{\text{Ag}}$ (rather
than merely $\Delta \gamma$) is gained in free energy per unit
area. For particles with nanodimensions, the capillary
forces associated with this reduction in surface area are
on the order of the theoretical strength of the material
[21]. We have estimated the rate at which nanoparticles
enter into the substrate by assuming that Ag atoms
diffuse from under the Co cluster to the surface along
the Ag/Co interface of width $\delta$. With the reasonable
assumption that the Co cluster remains nearly spherical,
it is straightforward to show using the procedure of Chu
et al. [22] for the sintering of two spheres that the time $t$
required for the cluster to burrow to a depth equal to 99%
of its diameter is

$$t = \frac{kT}{V_m \gamma_{\text{Ag}} \delta D} r^4.$$ \hspace{1cm} (2)

$\alpha$ is a geometric factor, which has a value of 0.8 in this
case. $V_m$ is the volume of one substrate atom, and $D$
is the diffusion coefficient along the Ag/Co interface.
$T$ is the substrate temperature and $k$ is the Boltzmann
constant. The same dependencies on $r$, $D$, and $\gamma_{\text{Ag}}$
in Eq. (2) are typical for processes that are dominated by
surface or interface diffusion but with different boundary
conditions having different numerical factors $\alpha$. The time
for two spheres of radius $r$ to sinter and form one sphere
by surface diffusion is given by Eq. (2) but with $\alpha = 0.6$
[23], while Coble creep [24] is described by Eq. (2) with
$\alpha = 0.2$ [25].

With the approximation that the diffusion coefficient $D$
in Eq. (2) along the cluster substrate interface is equal to
the geometric average of grain boundary self-diffusion at
600 K in polycrystalline Ag, $\delta D = 2.9 \times 10^{-22}$ m$^3$s$^{-1}$
[26], and Co, $\delta D = 7.6 \times 10^{-24}$ m$^3$s$^{-1}$ [27]. Eq. (2)
yields a time of less than 0.1 s for a cluster of 13 nm to
sink into the substrate. At room temperature, on the other
hand, the time required is of the order of months. These
rates fit nicely with our observations that no burrowing is
observed at room temperature even after $10^4$ s, while it occurs in less than 100 s at 600 K. The $r^4$ dependence in Eq. (2) explains, moreover, why this phenomenon has not been observed for larger particles. Note that increasing the particle size from 10 nm to 1 μm slows the sinking time by a factor of $10^8$, whereas increasing the temperature from 600 K to even the melting point only gains a factor of $10^4$.

The situation is somewhat more complicated for Co clusters on Cu(100) since the particle becomes coherent with the substrate. The strain energy, however, is not significant for these small particle sizes. The strain energy of a spherical Co cluster embedded coherently in a Cu matrix is only $5 \times 10^{-4}$ eV/Å$^3$ times the cluster volume [28]. For a cluster close to the surface, we confirmed by computer simulations that the strain energy is, in good approximation, proportional to the cluster volume already embedded in the film. Thus the strain energy becomes significant only for particles much larger than those in these experiments. The surface energies involved ($\gamma_{\text{Cu(100)}} = 2.2$ J/m$^2$ [17], $\gamma_{\text{Cu-Co(100)}} = 0.02$ J/m$^2$ [18], $\gamma_{\text{chem}} = 0.1$ J/m$^2$ [20]) again predict that the Co cluster will acquire an initial Cu coating. The burrowing time, according to Eq. (2) and $\delta D$ approximated by the geometric average of Co and Cu grain boundary diffusivity ($\delta D(\text{Cu}) = 2.8 \times 10^{-24}$ m$^2$ s$^{-1}$ at 600 K [27]), is less than 1 s. Since the Co particle reorients to become coherent with the Cu matrix, however, the diffusion along the Cu/Co interface may in fact be slower. The reorientation process itself was also rapid and was completed already by the time the particles could be imaged.

Finally, we argue against an alternative pathway that could lead to buried clusters. The clusters in principle can become buried on a local scale by surface diffusion of substrate atoms onto the side of the clusters. This surface structure would have thickness variations of the order of the average particle size unless they were further smoothened by the process suggested in Ref. [10], where atoms from the bottom part of the film diffuse through holes in the film to fill the space between particles. In analogy to Eq. (2) we estimate that this process would be a factor of $10^5$ to $10^7$ times slower than the burrowing on the basis of the length scales involved, which would be the interparticle distance for the driving force and the hole distance for the amount of material that has to be supplied. This slower rate is not offset by the faster surface diffusion. This mechanism, moreover, has other difficulties to explain our specific results: (i) Particles still remaining on the surface as seen in Fig. 2 could not be explained, and (ii) Refs. [6,10] do not observe diffusion through pinholes at temperatures as low as 600 K. Therefore we exclude this process here.

In conclusion, we have presented experimental evidence that Co nanoparticles in the 10 nm size regime sink below the surface when deposited on Ag(100) and Cu(100) surfaces at 600 K, and that this process is likely due to burrowing. Burrowing is driven by the extremely large capillary forces on the particles. This work suggests that burrowing should occur in all systems where the nanoparticles have a significantly higher surface energy than the substrate. If the particle had a smaller surface energy, it would simply wet the substrate. Immiscibility is not an essential feature.

We are grateful to N. Finnegan, T. Banks, S. Mayr, and R. D. Twesten for their help in characterizing our samples. The research was supported by the Department of Energy under Grant No. DEFG-96ER45439. Extensive use was made of the DOE supported Center for Microanalysis of Materials at UIUC. A grant of computer time from the National Center for Supercomputing Applications (NCSA) at UIUC is also acknowledged.

[25] The local stress normal to the boundary is assumed to be $2y/r$.
